Abstract

Document similarity measures are crucial components of many text analysis tasks, including information retrieval, document classification, and document clustering. Conventional measures are brittle: they estimate the surface overlap between documents based on the words they mention and ignore deeper semantic connections. We propose a new measure that assesses similarity at both the lexical and semantic levels, and learns from human judgments how to combine them by using machine learning techniques. Experiments show that the new measure produces values for documents that are more consistent with people's judgments than people are with each other. We also use it to classify and cluster large document sets covering different genres and topics, and find that it improves both classification and clustering performance.

Introduction

Accurate assessment of the topical similarity between documents is fundamental to many automatic text analysis applications, including information retrieval, document classification, and document clustering. Choosing a good similarity measure is no less important than choosing a good document representation (Hartigan, 1975). Commonly used techniques such as the Cosine and Jaccard metrics rely on surface overlap: in order to be related, documents must use the same vocabulary.

These existing measures treat words as though they are independent of one another, which is unrealistic. In fact, words are not isolated units but always relate to each other to form meaningful structures and to develop ideas. When reading, our thoughts constantly utilize relations between words to facilitate understanding (Altmann & Steedman, 1988). Without resolving word-level redundancies (i.e. synonymy) and ambiguities (i.e. polysemy), a similarity computation cannot accurately reflect the implicit semantic connections between words.

The alternative we investigate in this paper is to use concepts instead of words to capture the topics of documents, by creating a concept-based document representation model. “Concepts” are units of knowledge (ISO, 2009), each with a unique meaning. They have three advantages over words as thematic descriptors. First, they are less redundant, because synonyms such as *U.S.* and *United States* unify to the same concept. Second, they disambiguate terms such as *apple* and *jaguar* that have multiple meanings. Third, semantic relations between concepts can be defined, quantified, and taken into account when computing the similarity between documents—for example, a document discussing *endangered species* may relate to one on *environmental pollution* even though they may have no words in common.

The value of concepts and their relations has been recognized and exploited in many text processing tasks, including information retrieval (Milne, Witten, & Nichols, 2007), semantic analysis (Mihalcea, Corley, & Strapparava, 2006), document classification (Gabrilovich & Markovitch, 2005), and document clustering (Hu, et al., 2008; Huang, Milne, Frank, & Witten, 2008). Some authors even enrich document similarity measures based on lexical or conceptual overlap with semantic relations between concepts (Mihalcea, et al., 2006; Hu, et al., 2008). However, this is done in an ad hoc fashion, and the best way to employ such rich semantic knowledge remains unknown. To establish a more principled approach, we use supervised machine learning techniques to determine how to combine concepts and their semantic relations into a document similarity measure that reflects human judgment of thematic similarity.

We evaluate the learned measure in two types of tasks. First, we compare it with human judgments of document similarity in terms of the consistency it achieves with human raters. Empirical results show that it produces values for documents that are more consistent with people's judgments than people are with each other. Second, we use it to classify and cluster documents from different sources. Empirical results show that it outperforms existing overlap-based similarity measures by obtaining better classification accuracy and document clusters with greater cohesion. Our results provide strong support for the learned measure's generality: it can be used effectively on documents with different topics and genres, from different subject domains, and with varying lengths.

The next section reviews related work. Then we introduce our framework and its key components: how concepts in documents can be identified and used to represent them, and how their semantic relations can be quantified and exploited to calculate

document similarity. Next we present a new approach for automatically learning the document similarity measure from human judgments. Finally we describe the evaluations performed and discuss the results.

Related Work

The standard document representation technique is the vector space model (Salton, Wong, & Yang, 1975). Each document is expressed as a weighted high-dimensional vector, the dimensions corresponding to individual features such as words or concepts. When words are used, the result is called the *bag-of-words* model. It is brittle because of redundancy, ambiguity and orthogonality; the first because synonyms are not unified, the second because no account is taken of polysemy—one word can have different meanings—and the third because semantic connections between words are neglected, which not only encompass the synonymy and polysemy relations but extend to the more general sense of two words being semantically related.

Alternative features, such as phrases (Caropreso, Matwin, & Sebastiani, 2001), term clusters (Slonim & Tishby, 2000), and statistical topic models (Hofmann, 1999; Blei, Ng & Jordan, 2003) have been proposed to solve these problems. However, phrases, being sequences of words, can also be ambiguous, although they are usually more specific than single word terms. For example, *access point* usually refers to a device used to connect to a wireless network, yet it can also mean a rocky point on the Anvers Island of Antarctica.

Term clustering and topic modeling techniques seek groups or combinations of terms that are strongly associated with one another in a given document collection, each cluster or combination presumably representing a latent topic hidden in the

documents. Their effectiveness depends heavily on the input data. Also, it is hard to interpret which topic a term cluster or combination represents (Hofmann, 1999), let alone connect the topics. Therefore these techniques cannot easily be generalized to fresh data, particularly documents with previously unseen terms and ones from different document collections.

Concepts—units of knowledge—provide a neat solution to these problems. Each one represents a unique meaning and is thus unambiguous, and because of this, semantic relations between concepts can be defined and quantified in order to address the orthogonality problem. Concepts make more succinct descriptors than words.

Concepts, organized and structured according to the relations among them, form a concept system. Given the standard definition of concepts as units of knowledge, encyclopedias like Britannica (Britannica, 2011) and Wikipedia (Wikipedia, 2011) are promising sources of concept knowledge. They provide extensive coverage of almost every branch of knowledge, with a particular focus on factual explanations of the concepts (Hartmann & James, 1998). Britannica is available only commercially, so we focus on the freely accessible Wikipedia. Some resources such as the Medical Subject Headings (MeSH) and Agrovoc are domain dependent. Research and applications of these systems are usually restricted to processing texts from that domain (Zhu, Zeng, & Mamitsuka, 2009; Bloehdorn & Hotho, 2004). Thus, they are not considered in this paper, although the techniques developed here can be directly applied to such resources.

Wikipedia is a collaboratively developed online encyclopedia in which each article succinctly describes a single topic that we treat as a “concept.” The English version contains 3.7 million articles.¹ Because of its open accessibility and comprehensive world knowledge, Wikipedia has been extensively and effectively exploited to

facilitate better understanding of documents. Studies show that Wikipedia-based concept representations are more effective than word vectors when assessing the semantic relatedness between documents (Gabrilovich & Markovitch, 2007; Yeh, Ramage, Manning, Agirre & Soroa, 2009), and have been applied successfully to information retrieval (Milne, et al., 2007; Potthast, Stein, & Anderka, 2008), text classification (Gabrilovich & Markovitch, 2005; Wang & Domeniconi, 2008), and document clustering (Hu et al., 2008; Huang, et al., 2008).

Lexical resources have also been exploited to identify concepts in running text. These provide information about individual words, rather than general conceptual knowledge (Gabrilovich & Markovitch, 2009). In particular, WordNet (Miller, 1995) is a lexical ontology of common English word knowledge expressed in terms of concepts called synonym sets (synsets), maintained by experts at Princeton University. The most recent version (3.0) contains about 118,000 concepts. It also encodes semantic relations among concepts, such as *generic* (hypernymy) and *partitive* relations (meronymy). Concept representations based on WordNet have been utilized to quantify semantic relatedness between documents (Mihalcea, et al., 2006; Mohler & Mihalcea, 2009), and in information retrieval (Gonzalo, Verdejo, Chugur, & Cigarran, 1998; Voorhees, 1998), text classification (Scott & Matwin, 1999; Gabrilovich & Markovitch, 2004), and document clustering (Hotho, Staab, & Stumme, 2003; Recupero, 2007).

Concept-based document representations solve the redundancy and the ambiguity problems but are still basically orthogonal. To address this problem, some expand the representation to incorporate concepts that are absent from a document but closely related to ones that it mentions (Bloehdorn & Hotho, 2004; Gabrilovich & Markovitch, 2005; Yeh et al., 2009; Recupero, 2007), and others only consider

relations that are pertinent to the documents currently being compared (Hu, et al., 2008). The decisions governing which relations should be considered and how are usually ad hoc. For example, Bloehdorn & Hotho (2007) expand to concepts that are more general than those mentioned in the document, and restrain the expansion to be within a certain depth in a hierarchy. Hu’s system considers several relations, including hierarchical and associative relations, each restricted to a certain range, and the formula for combining them is determined empirically through experimental trials.

In contrast, our work takes explicit account of semantic relations between concepts, in a principled way. Related methods in the literature include ESA (explicit semantic analysis) (Gabrilovich & Markovitch, 2005) and its successor ESA-G (Yeh et al., 2009), both of which index documents with Wikipedia concepts based on full-text analysis. ESA indexes a document with Wikipedia articles that have certain surface overlap with it. ESA-G enriches ESA with hyperlink structure information by using an iterative random walk over Wikipedia’s hyperlink graph that is initialized with the Wikipedia concepts assigned to a document by ESA. Because they require processing the fulltext of Wikipedia articles, they are computationally more expensive than our method, which does not involve fulltext analysis. We compare our measure with these techniques in the evaluation section.

We use both WordNet and Wikipedia to identify concepts in documents and to relate different concepts. Both are domain independent, yet different techniques are required because they have distinct structure and characteristics. We will explain how each is used to identify concepts in free-text documents after introduce our framework in the following section.

Framework

FIGURE 1 illustrates the general process of creating and applying our document similarity measure. Given a document collection, we first list all the possible document pairs. Given each pair, the first step creates two independent representations by extracting words and concepts from the documents. The feature generation step takes the representations as input, extracts features that describe the resemblance between the two documents at different levels, and outputs a feature vector. The feature vectors for different document pairs are used to build the similarity measure in the training phase, and the resulting model is then applied to previously unseen document pairs to predict their thematic similarity.

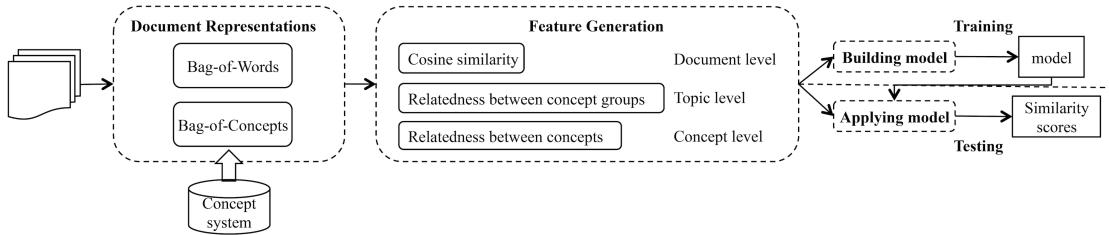

FIGURE 1 The process of creating and applying our document similarity measure.

The following section explains the document representations. Several features involve measuring the semantic relatedness between concepts, thus we will first describe the measures we use for WordNet and Wikipedia and then introduce the features.

Document Representation

Documents are represented at the lexical and semantic levels by the *words* and *concepts* they contain. This creates two independent representations, called *bag-of-words* and *bag-of-concepts* respectively. To create the former, documents are segmented into tokens based on white space, paragraph separators and punctuation

marks. Then all words are extracted and stemmed (Porter, 1980), stopwords are removed, and the number of occurrences of each word is counted.

To create the bag-of-concepts representation, the concepts in the document are identified. First, an index vocabulary is extracted from each concept system (Wikipedia and WordNet) whose entries associate concepts with lists of expressions that could be used to refer to it in running text (Huang, et al., 2008). For Wikipedia, the expressions come from the redirects and anchor phrases that point to a Wikipedia article, and for WordNet they are the synonyms in a synset. For example, WordNet associates the concept “a machine for performing calculations automatically” with 6 expressions, *computer*, *computing machine*, *computing device*, *data processor*, *electronic computer* and *information processing system*; whereas Wikipedia associates it with more than 100, from synonyms like *computer systems* to common spelling errors like *computar*.

Concepts mentioned in a document are identified in two steps: *candidate identification* and *sense disambiguation*. In the first, all word sequences up to the maximum length of the index vocabulary are extracted, provided they do not cross boundaries such as paragraph separators. Each sequence is matched against the vocabulary. A positive match connects it to the concept or concepts associated with that expression, which constitute the set of concept candidates. For example, *pluto* generates (at least) three concept candidates: the dwarf planet in the Solar System, the cartoon character, and the Roman god of the underworld. The second step disambiguates the intended meaning of a polysemous term and retains only the concept that represents this meaning.

For Wikipedia, the disambiguation process establishes how closely a concept candidate relates to its surrounding context and chooses the most highly related as the

intended sense (Milne & Witten, 2008a). For WordNet, we simply choose the most common sense of a concept as its intended sense, because experimentation showed this to be the most effective method (Huang, 2011; Hotho, et al., 2003). In either case, the outcome is the bag-of-concepts representation of the document, comprising the set of concepts it mentions, synonyms having been mapped to the same concept and polysemous terms having been disambiguated as described above, along with a count of the number of occurrences of each concept.

Semantic Connections between Documents

Researchers have long been aware of the redundancy, ambiguity and orthogonality problems (Hartigan, 1975). However, they cannot be solved using the bag-of-words model. The concept-based model rectifies the situation. The previous section explained how concepts address redundancy and ambiguity; now we focus on orthogonality. More specifically, we quantify how closely concepts relate to each other and integrate this into a document similarity measure. As a result, documents do not have to mention the same words or concepts in order to be judged similar.

Concept Relatedness Measure

Measuring semantic relatedness between concepts is a challenging research problem in its own right and has been studied extensively using both WordNet and Wikipedia (Resnik, 1995; Leacock & Chodorow, 1997; Strube & Ponzetto, 2006; Gabrilovich & Markovitch, 2007; Milne & Witten, 2008b). There are three general requirements for a concept relatedness measure to be applicable in our framework. First, it should be accurate, an appropriate measure of accuracy being consistency with human judgments of relatedness. Second, it should apply to all members of the concept system, simply because any concept could be encountered in practice. Third,

it should be symmetric. Although asymmetry may be desirable in some tasks (Tătar, Şerban, Mihiş, & Mihalcea, 2009), the tasks that we apply the relatedness measure to predominantly use symmetric relationships. Relatedness values also need to be normalized to the range from 0 (completely unrelated) to 1 (synonymous).

For WordNet concepts we use Leacock and Chodorow's path-length measure LCH (Leacock & Chodorow, 1997), while for Wikipedia we use Milne and Witten's hyperlink-structure measure WLM (Wikipedia Link-based Measure) (Milne & Witten, 2008b). They both satisfy all three requirements. They are either more accurate than the alternatives in terms of consistency with human judgment or as accurate but significantly more efficient (Strube & Ponzetto, 2006; Milne & Witten, 2008b).

LCH utilizes WordNet's concept taxonomies, and defines semantic distance as the number of nodes along the shortest path between two concepts, normalized by the depth of the taxonomy. Formally, the relatedness between concepts A and B is defined as

$$LCH(A, B) = -\log \frac{\text{length}(A, B)}{2D}$$

where $\text{length}(A, B)$ is the number of nodes along the shortest path between A and B and D is the maximum depth of the taxonomy. If A and B belong to different taxonomies (for example A is a noun and B is a verb), or either concept does not exist in any taxonomy (for example A is an adjective), the relatedness is set to zero.

WLM has two components, modeling incoming and outgoing hyperlinks respectively. Given two Wikipedia articles A and B , denote the sets of hyperlinks found within them by A_{out} and B_{out} , and the sets of hyperlinks that are made to them by A_{in} and B_{in} . WLM's first component uses the cosine measure between A_{out} and

B_{out} :

$$WLM_{out}(A, B) = \frac{\sum_{l \in A_{out} \cup B_{out}} w(l, A) \times w(l, B)}{\sqrt{\sum_{l \in A_{out}} w(l, A)^2} \times \sqrt{\sum_{l \in B_{out}} w(l, B)^2}}.$$

Here $w(l, A)$ is the weight of a link l with respect to article A , which is 0 if

$l \notin A$ and $\log \frac{|W|}{|T|}$ otherwise, where $|W|$ is the total number of articles in Wikipedia

and $|T|$ the number that link to the target of l . This resembles inverse document frequency weighting (Manning, Raghavan, & Schütze, 2008). Incoming links are modeled after the *normalized Google distance* (Cilibrasi & Vitányi, 2007). Formally,

$$WLM_{in}(A, B) = 1 - \frac{\max(\log |A_{in}|, \log |B_{in}|) - \log |A_{in} \cap B_{in}|}{\log(|W|) - \log(\min(|A_{in}|, |B_{in}|))}$$

where $A_{in} \cap B_{in}$ denotes the set of hyperlinks that link to both A and B . WLM computes overall relatedness as the average of these two components.

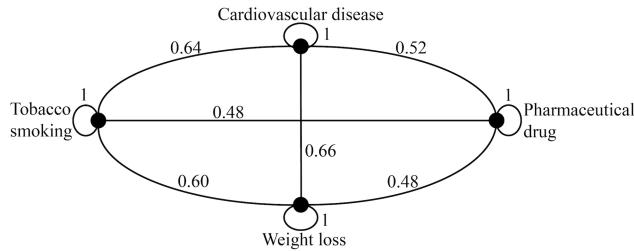

FIGURE 2 Example concept graph.

Context Centrality

Next we integrate concept relatedness into a full measure of document similarity. A key notion is the *centrality* of a concept with respect to a given context, where a “context” is the set of concepts in a document. Centrality indicates the concept’s relevance to the context, and we use it to enrich the overlap-based measure.

Concepts and their connections are represented by a weighted undirected graph

whose vertices are concepts and whose edges connect pairs of concepts, weighted by their relatedness. FIGURE 2 shows an example. When two concepts have zero relatedness, we create an edge with zero weight. We also create an edge from each vertex to itself, with a weight of 1, to cope with the situation when the graph has only one concept. The concepts themselves are weighted too, the weights being either binary—0 and 1 indicating the concept’s absence and presence respectively—or a numeric score reflecting how often the concept is mentioned in the context. We call these the *binary* and *weighted* schemes.

We compute the context centrality of each concept within the document by calculating the average edge weight of its vertex in the graph. Formally, denote the weight of concept c in a set of concepts C by $w(c, C)$ (either binary or numeric, as noted above). The centrality of c with respect to the context C is defined as

$$CC(c, C) = \frac{\sum_{c_j \in C} rel(c, c_j) \times w(c_j, C)}{\sum_{c_j \in C} w(c_j, C)},$$

where $rel(c, c_j)$ is the relatedness between c and c_j . Context centrality is normalized between 0 and 1, and higher values indicate that the concept is closer to the *center* of the graph—i.e., more closely related to the context.

Learning Document Similarity

We use a total of 17 features to characterize document similarity, representing four different aspects: *overall similarity*, *context centrality*, *strongest connection* and *concept groups*. The first bases similarity on the entire bag of concepts; the second and third utilize the strength of semantic connections beyond the documents’ surface forms; and the fourth takes into account the relations between “topics,” which we

define as groups of closely related concepts.

The learned similarity measure takes as input a pair of documents and produces a score between 0 and 1, the former indicating that the concepts in the documents are completely different and the latter that they are identical. The measure works in three steps: *document representation*, *feature extraction* and *similarity calculation*. The first step generates the bag-of-words and bag-of-concepts representations discussed above; the second calculates feature values that characterize the thematic resemblance between documents; and the third uses a model to compute similarity according to the feature values. This model is first built from training data—document pairs with their thematic similarity rated by human raters—and then applied to previously unseen document pairs. It encodes how the features should be combined to best model human judgment.

Next we introduce the features. Then we describe how the model is built from training data, and how it is applied to fresh documents.

Features

Each of the four aspects mentioned above consists of several features, reflecting the various perspectives the aspect encompasses. Each feature is expressed with one or two *attributes* that correspond to dimensions in the vector representing the document pair. The 17 features result in the 25 attributes listed in TABLE 1. These attributes comprise the vector that describes the similarity between a pair of documents.

Overall similarity

The first feature type computes the similarity between documents based on the overall similarity of the entire bag of words or concepts they mention. For bags of words we use the cosine measure, and for bags of concepts we develop a new

enriched measure that takes into account semantic relations between the concepts. This generates two features, *CosineWords* and *EnrichedConcepts* (F1 and F2 in TABLE 1), each of which corresponds to one attribute.

Level	Aspect	ID	Feature	Number of attributes
Document-level	Overall similarity	F1	CosineWords	1
		F2	EnrichedConcepts	1
Concept-level	Context centrality	F3	MaxLocal	2
		F4	MinLocal	2
		F5	AvgLocal	2
		F6	SDLocal	2
		F7	MaxRelative	2
		F8	MinRelative	2
		F9	AvgRelative	1
		F10	SDRelative	2
		F11	MaxRel	1
		F12	MaxNORel	1
Topic-level	Concept groups	F13	AvgGroupSize	2
		F14	MaxGroupRel	1
		F15	MinGroupRel	1
		F16	AvgGroupRel	1
		F17	SDGroupRel	1
Total		F1–F17		25

TABLE 1 Features used for learning document similarity.

Cosine similarity measure

The cosine measure calculates the similarity between two documents as the cosine of the angle between their corresponding word vectors (Salton, et al., 1975). Formally, if \vec{d}_A and \vec{d}_B are the word vectors of documents d_A and d_B , their similarity is computed as

$$\text{cosine}(d_A, d_B) = \frac{\overrightarrow{d_A} \cdot \overrightarrow{d_B}}{|\overrightarrow{d_A}| \cdot |\overrightarrow{d_B}|} = \frac{\sum_{t \in V} w(t, d_A) \times w(t, d_B)}{\sqrt{\sum_{t \in V} w(t, d_A)^2} \sqrt{\sum_{t \in V} w(t, d_B)^2}},$$

where $w(t, d_A)$ is the weight of word t in d_A —that is, the $tf \times idf$ weight, based on the number of occurrences of t in d_A —and V denotes the size of the vocabulary of the document collection. Evidence from various applications shows that this formula effectively measures inter-document similarity (Willett, 1983; Rorvig, 1999; Lee, Pincombe, & Welsh, 2005).

Like many other measures, the cosine measure does not take connections between features into account. Thus we only apply it to the word-based representation. Despite its limitations, this feature (F1) contributes to the learned measure's robustness, especially in the extreme (and extremely rare) case where no concepts are detected in the input document.

Semantically enriched similarity

One way of enriching document similarity with semantic relations is to expand each document's representation to include new concepts based on those it already mentions: both more generic concepts such as hypernyms of existing ones (Bloehdorn & Hotho, 2004; Recupero, 2007), and closely related concepts (Hu, et al., 2008). For example, FIGURE 3 shows two documents, the Wikipedia concepts identified in them (italicized, on the right), and the phrases in the documents that evoke the concepts (in bold). The documents have no concepts in common, yet the first mentions *cardiovascular disease* and the second mentions *coronary heart disease*, both of which belong to the same Wikipedia category, *cardiovascular diseases*. The two documents could be related by expanding both representations to include this common category. Of course, the expansion must be restricted somehow—perhaps to

concepts within a certain range.

D1	By giving up smoking , losing weight , and becoming more active people can reduce their risk of cardiovascular disease two to three-fold, which largely outweighs the risks of taking the medications .	smoking → <i>Tobacco smoking</i> losing weight → <i>Weight loss</i> cardiovascular disease → <i>Cardiovascular disease</i> medications → <i>Pharmaceutical drug</i>
D2	In the UK , there are 2 million people affected by angina : the most common symptom of coronary heart disease . Angina pectoris , commonly known as angina , is severe chest pain due to ischemia (a lack of blood , hence a lack of oxygen supply) of the heart muscle .	the UK → <i>United Kingdom</i> angina → <i>Angina pectoris</i> coronary heart disease → <i>Coronary heart disease</i> chest pain → <i>Chest pain</i> ischemia → <i>Ischemia</i> blood → <i>Blood</i> oxygen → <i>Oxygen</i> heart muscle → <i>Cardiac muscle</i>

FIGURE 3 Documents about *smoking* and *health* respectively.

For example, the concept *smoking*, which is literally mentioned in document D1, might be expanded to include hypernyms like *addiction* and *habits*, and closely related concepts such as *tobacco*, *cigarette*, and *nicotine*. However, most of these expanded concepts are irrelevant for connecting document D1 with D2, which discusses coronary heart disease.

An alternative approach to enriching document similarity is to focus on the comparison itself, and take account of the context that the comparison provides. The orthogonality problem when comparing two documents can be addressed by enriching each document with the concepts that have been identified in the other: here, enriching D2 with the four concepts in D1, and enriching D1 with the eight concepts in D2. We utilize the measures of concept relatedness explained previously to determine the weights of the enriched concepts.

Given two documents, we enrich each by adding all the new concepts that are identified in the other. The weight of each newly added concept is based on both its most closely related concept in the document to which it has been added, and its

centrality with respect to that document. Formally, given documents d_A and d_B with concept sets C_A and C_B , we first enrich C_A with concepts from d_B that are not mentioned in d_A . For each such concept c_e ($c_e \in C_B$ and $c_e \notin C_A$), the first component—its strongest connection with C_A —is denoted by c_e^A , that is, $c_e^A = \max_{c \in C_A} rel(c_e, c)$, and the second component is its centrality with C_A : $CC(c_e, d_A)$. The enriched concept c_e 's weight in d_A is

$$w_e(c_e, d_A) = w(c_e^A, d_A) \times rel(c_e^A, c_e) \times CC(c_e, d_A),$$

where $w(c_e^A, d_A)$ is c_e 's most related concept c_e^A 's weight in d_A , which is also weighted with the $tf \times idf$ scheme based on its occurrence frequencies, and $rel(c_e^A, c_e)$ is their relatedness. Document d_B is enriched in the same way with concepts from d_A that are not mentioned in d_B . Then the cosine measure is used with the enriched representations.

Both components of a newly added concept's weight—its strongest semantic connection and its context centrality with the document—are plausibly necessary. The former represents the most likely strength of the connection that the concept makes between the two documents, while the latter adjusts it according to the concept's importance in the document to which it has been added.

Context centrality

The second group of features characterizes the distribution of the context centrality values of concepts in each document. We calculate centrality with respect to two distinct contexts: the one surrounding a concept, which reflects how central it is to the document that mentions it; and the context provided by the comparison document, which reflects the concept's relevance to the comparison itself. We call these *local*

and *relative* centrality, respectively.

Four statistics are used to describe the overall distribution of centrality values, *minimum*, *maximum*, *average* and *standard deviation*, and these are applied to both local and relative centrality to yield features F3–F6 and F7–F10 in TABLE 1. The distribution of local centrality reveals the cohesiveness of a document, while the distribution of relative centrality characterizes the overall semantic relatedness between the documents. For example, if two documents share similar topics, a considerable proportion of their concepts should have high relative centrality, resulting in a large average and a small standard deviation.

The first two features—minimum and maximum—are trivial to obtain. The average centrality is the mean of the centrality values of all concepts, and the standard deviation is computed as

$$s = \sqrt{\frac{1}{|C|-1} \sum_{c_i \in C} (CC(c_i, C) - \overline{CC})^2}$$

where $|C|$ is the number of concepts in the context, $CC(c_i, C)$ is concept c_i 's centrality with respect to C , and \overline{CC} is the average context centrality of all concepts in C . Each feature yields two attributes except for the average relative centrality (F9), which is symmetric.

Strongest connection

The centrality features assess relations between one concept and a set of concepts: for example, maximum centrality identifies which concept has the strongest *overall* relatedness to *all* concepts in a group. The third group in TABLE 1 concerns one-to-one relations, which also provide useful information about document similarity. There are two such features: the maximum relatedness between single concepts in the

documents ($MaxRel$, F11) and the maximum relatedness between concepts that appear in one document but not the other ($MaxNORel$, F12). The two are the same unless the documents have at least one concept in common, in which case $MaxRel = 1$.

For example, the strongest connection between D1 and D2 in FIGURE 3 is between *cardiovascular disease* and *coronary heart disease*, whose relatedness value is 0.71. Because the two documents have no concepts in common, $MaxRel = MaxNORel = 0.71$ for this example.

Concept groups

Concepts mentioned in the same document are not only related but can form their own structures: closely related concepts are often used together when describing a topic that they are all associated with. For example, a document explaining *oil spill* might mention alternative references to oil (such as *petroleum*, *gasoline*, *diesel*), some oil companies (such as *Shell* and *BP*), and oil's influence on species like *seabirds* and *marine mammals*. These three groups (*oil spill* and so on, oil companies, and wildlife species) each represent a more detailed aspect of the document's topic. Documents that share similarity in any aspect are somewhat similar to the document in question, and those that mention all three aspects are even more alike.

To capture this effect we cluster concepts according to their relatedness to each other, combining closely related ones into the same group and separating those with tenuous links into different groups. Each group, like the three discussed above, reflects a topic or a subtopic mentioned in the document. From these we generate features that describe inter-document relations at the *topic* level, which is intermediate between the document and concept levels examined previously.

Specifically, concepts are clustered to form *cliques*—complete subgraphs—in order to make the topics (or subtopics) as coherent as possible. Again, documents are

modeled by weighted undirected graphs with concepts as vertices. Unlike the graphs used to model context centrality, which connect every concept to all others, here only those whose relatedness exceeds a certain threshold (0.5 in used throughout this paper) are connected. The maximal cliques of this graph give the concept groups we seek. Every pair of concepts assigned to the same group exceeds this threshold, and no other concept can be added to any of these groups.

For example, FIGURE 4 shows the groups with at least two concepts identified from D1 and D2 (FIGURE 3) with a relatedness threshold of 0.5. D1 contains just one group, and it is closely related to only the first of the three groups in document D2. *Blood* appears in two of D2’s groups because *ischemia*, *cardiac muscle* and *oxygen* are insufficiently related for the groups to be merged.

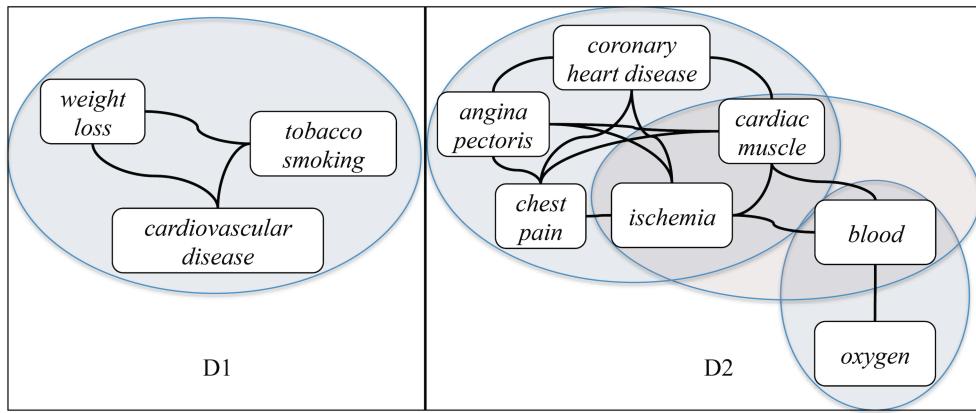

FIGURE 4 Concept groups in the documents in FIGURE 3.

Concepts that cannot be assigned to any group can either form a singleton—a group by itself—or be ignored. We call these the *full* and *strict* schemes respectively. For example, document D1 has one group in the *strict* scheme and two in the *full* scheme. Full schemes capture every aspect of a document, even the unimportant ones. This favors situations when two documents are highly similar: even their less important aspects can be alike and strongly related. In contrast, strict schemes highlight the most prominent aspects of a document and can reduce computation

overhead by avoiding relatedness computation between singleton groups.

Several features can be derived from these concept groups. One is the average group size for each document (F13 in TABLE 1). As with centrality, we use the maximum, minimum, average, and standard deviation statistics to characterize the distribution of relatedness between groups (F14–F17).

The relatedness between two concept groups is the weighted average of the relatedness between their member concepts. Formally, let $G_A = \{\varsigma_1, \dots, \varsigma_p\}$ and $G_B = \{\varsigma_1, \dots, \varsigma_q\}$ be the concept groups (ς) identified from documents d_A and d_B .

The relatedness between ς_h from d_A and ς_i from d_B is calculated as:

$$rel(\varsigma_h, \varsigma_i) = \frac{\sum_{c_i \in \varsigma_h} \sum_{c_j \in \varsigma_i} w(c_i, d_A) \times w(c_j, d_B) \times rel(c_i, c_j)}{|\varsigma_h| \times |\varsigma_i|},$$

where $|\varsigma|$ refers to the size of group ς and is calculated as $\sum_{c \in \varsigma} w(c, d)$. Here, $w(c, d)$ is concept c 's weight in document d that produces ς , and is either 1 or 0 to indicate the concept's presence or absence (the *binary* version), or a score based on its number of occurrences (the *weighted* version). The average group relatedness is the mean of every possible pair of concept groups weighted by each group's size:

$$grouprel(d_A, d_B) = \frac{\sum_{\varsigma_h \in G_A} \sum_{\varsigma_i \in G_B} rel(\varsigma_h, \varsigma_i) \times |\varsigma_h| \times |\varsigma_i|}{\sum_{\varsigma_h \in G_A} |\varsigma_h| \sum_{\varsigma_i \in G_B} |\varsigma_i|}.$$

If no concept group is found for a document (in the *strict* scheme), the average group relatedness is set to -1 to differentiate this from the case where none of the groups are related, in which case $grouprel(d_A, d_B)$ is zero.

Training Data

Our strategy is to build a model that uses these features to predict document similarity, and for this we need training data. Unfortunately, little data on manually rated thematic document similarity is available, and we know of only one dataset with a substantial number of human raters, referred to as HE50 (Lee, et al., 2005; Pincombe, 2004).

HE50 consists of fifty short news documents from August 2002, selected from a group of articles taken from the Australian Broadcasting Corporation's news mail service. The documents are quite short—between 51 and 126 words—and contain a total of 1583 distinct words after case-folding. Assessments of word distribution show that they are normal English documents (Pincombe, 2004). The documents were paired in all possible ways, generating 1225 pairs (excluding self pairs).

The judges were 83 students from the University of Adelaide. Document pairs were presented in random order, and the order of documents within each pair was also randomized. Students rated the pairs on an integer scale from 1 (highly unrelated) to 5 (highly related), each pair receiving 8–12 human judgments. Judgments were averaged and normalized to [0,1]. FIGURE 5 shows the distribution of the normalized ratings.

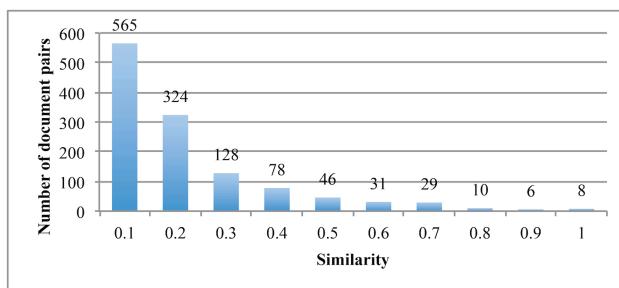

FIGURE 5 Distribution of averaged human ratings in the HE50 dataset.

Inter-labeler consistency is assessed in terms of Pearson's linear correlation

coefficient. Lee et al. show that the raters' judgments are quite consistent throughout the task and with each other: on average, raters have 0.6 correlation with one another. This dataset has become the benchmark for evaluating document similarity measures. One aim is to make automated measures as consistent with humans as humans are among themselves, and this inter-rater consistency serves as a baseline.

Regression Algorithms

We use regression algorithms to build a model that makes numeric predictions based on numeric values. We have experimented with several such algorithms: linear regression, support vector machines for regression (abbreviated SVMreg) (Smola & Schölkopf, 2004), the Gaussian process for regression (Rasmussen & Williams, 2006), and these four algorithms applied with forward stagewise additive modeling for regression (Hastie, Tibshirani, & Friedman, 2009). Performance is measured in terms of consistency with human judgments. The best results were achieved with support vector machines using the radial basis function kernel; incorporating additive regression improves performance only slightly and the improvement is not statistically significant. Thus all the results that follow were obtained with the SVMreg regressor alone (with epsilon=1.0E-12, C=1.0, and gamma=0.01 for the RBF kernel). All attributes are first standardized to have zero mean and unit variance, except the class attribute—the average rated similarity.

Evaluation Strategy

We evaluate the learned measure against human judgment, and we also evaluate it in specific applications. The former investigates whether the measure is able to predict thematic document similarity as consistently as humans, and also explores the effectiveness and predictive ability of the two concept systems—WordNet and

Wikipedia—and of the individual features. The latter is an important addition to evaluation against human judgment (Budanitsky & Hirst, 2001). It tests the measure’s effectiveness in different scenarios by applying it to different datasets and to document classification and clustering, which are both tasks that require a document similarity measure. This is important because the training dataset (HE50) is tiny and any measure learned from it will overfit unless it generalizes to other tasks and documents.

Evaluation Against Human Judgments

Like other researchers, we use Pearson’s linear correlation coefficient to measure the consistency between the predicted similarity and the gold standard—the average similarity as judged by human raters. The coefficient for two samples X and Y with n values and means \bar{X} and \bar{Y} is defined as:

$$r = \frac{\sum_{i=1}^n (X_i - \bar{X})(Y_i - \bar{Y})}{\sqrt{\sum_{i=1}^n (X_i - \bar{X})^2} \sqrt{\sum_{i=1}^n (Y_i - \bar{Y})^2}}.$$

TABLE 2 summarizes results in the literature on this dataset. Lee et al. (2005) found the cosine measure with the bag-of-words representation to yield a correlation of 0.42 with the gold standard, with only trivial differences between different similarity measures (including Jaccard). Their best result was achieved using latent semantic analysis on a larger collection of 364 documents, also from Australian Broadcasting Corporation news. Document vectors are transformed to a new feature space consisting of the latent topics identified in the larger set, and the cosine measure is used with the new vectors. As TABLE 2 shows, this technique is as consistent with an average human rater as the raters are with themselves. None of the bag-of-words similarity measures approach this level. Furthermore, research has shown that

estimates of inter-rater consistency based on partial document sets can be over-optimistic (Westerman, Cribbin, & Collins, 2010), which bolsters our method’s performance.

TABLE 2 Performance on the HE50 dataset.

Method	Pearson’s correlation coefficient
Inter-rater (Lee et al., 2005)	0.6
Bag of words with cosine measure (Lee et al., 2005)	0.42
Baselines Latent Semantic Indexing (Lee et al., 2005)	0.6
Explicit Semantic Analysis (ESA) (Gabrilovich & Markovitch, 2005)	0.72
Explicit Semantic Analysis-Graph (ESA-G) (Yeh et al., 2009)	0.77
Our method	0.808

Gabrilovich and Markovitch (2005) and Yeh et al. (2009) also report results on the HE50 dataset. Both their systems, ESA and ESA-G, represent documents as vectors of Wikipedia concepts and use the cosine measure; both yield a greater correlation with human raters than the average inter-rater agreement. These are the best-reported results on this dataset. These two methods and the inter-rater consistency comprise the three baselines for assessing our learned similarity measure.

Evaluation Setup

Each document is represented in three different ways: a bag of words and bags of concepts based on Wikipedia and WordNet. The average bag sizes per document are 37.1 words, 13.1 Wikipedia concepts and 39.2 WordNet concepts, for a total of 1187 words, 492 Wikipedia concepts and 1201 WordNet concepts.

All results reported below are averaged over five independent runs of stratified 10-fold cross-validation, to help reduce the possibility of overfitting the learned measure

to the tiny HE50 dataset. In each run the regression algorithm was trained on 90% of the document pairs (1102 examples) and tested on the remaining 10% (123 examples). To indicate the predictive capability of the learned model on new data, performance was measured on the held-out test set. Paired corrected resampled t -tests (Nadeau & Bengio, 2003) were used to establish statistical significance at a confidence level of 0.05.

Overall Consistency with Human Judgment

Our best model achieved an average correlation of 0.808 with the human ratings, ranging from 0.66 to 0.88. FIGURE 6 plots the similarity predicted by the best learned measure, using the Wikipedia-concept-based document representation, against that of human raters, and the ideal case would be a diagonal line from (0,0) to (1,1). The high correlation is apparent: its value of 0.808 exceeds both the inter-rater consistency and the state-of-the-art result obtained by Yeh et al. (2009). The upper right and lower left corners show that the learned measure agrees particularly well with human judgment on highly similar and highly dissimilar document pairs. Most points are concentrated at the lower left corner, because in this small dataset most documents have different topics. In fact, each document has an average of only 3.1 other documents whose manually rated similarity exceeds 0.5.

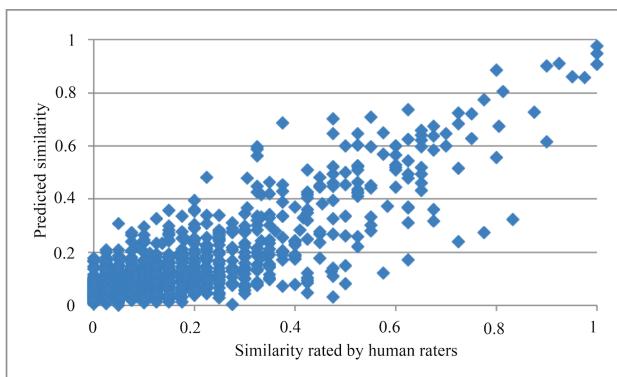

FIGURE 6 Correlation between predicted similarity and that of human raters.

WordNet Versus Wikipedia

The learned measure's correlation with human judgment is only 0.611 using the WordNet-based concept model, suggesting that Wikipedia concepts and the WLM concept relatedness measure are more effective than their WordNet counterparts in this task, and that Wikipedia's world knowledge is more relevant to thematic document similarity than WordNet's lexical knowledge. While the WordNet model did little better than people (0.6, see TABLE 2), it roundly outperforms the bag-of-words representation using cosine similarity (0.42).

Predictive Power of Individual Features

The predictive power of an individual feature is assessed from the performance of the regression model learned from that feature alone. TABLE 3 shows the individual predictability of the 17 features when Wikipedia concepts are used, along with some combinations.²

The difference between F1 and F2 indicates that the new representation is more discriminative than the bag-of-words model with the usual cosine measure—which is remarkable, because there are more than twice as many distinct words as there are concepts. Furthermore, F2's improvement over F1 is statistically significant.

The *context centrality* section of TABLE 3 shows that relative centrality is far more informative than local centrality, with a dramatic difference in the performance of both individual features and their combinations (*LocalCentralityCombined* and *RelativeCentralityCombined*).

Local centrality focuses on the quality of an individual document. It is a measure of how homogenous a document is; of how much it follows a single thread. Relative centrality, in contrast, focuses on the relation between two documents; on whether

they talk about closely related topics. Intuitively, relative centrality was always going to be the more useful measure. After all, our end goal is to measure the relatedness between two documents. This is born out in TABLE 3, where minimum relative centrality on its own approaches the performance of ESA (0.7 vs. 0.72 correlation).

TABLE 3 Predictive value of individual features (using Wikipedia concepts).

Aspect	ID	Feature	Pearson's correlation	
			Binary	Weighted
Overall similarity	F1	CosineWords	0.57	
Context centrality	F2	EnrichedConcepts	0.717	0.710
	F3	MaxLocal	-0.039	-0.001
	F4	MinLocal	-0.043	0.038
	F5	AvgLocal	0.374	0.045
	F6	SDLocal	0.022	0.004
		<i>LocalCentralityCombined</i>	0.155	0.174
	F7	MaxRelative	0.691	0.685
	F8	MinRelative	0.703	0.707
	F9	AvgRelative	0.327	0.320
	F10	SDRelative	0.679	0.657
Strongest connection		<i>RelativeCentralityCombined</i>	0.725	0.711
		<i>CentralityCombined</i>	0.774	0.759
	F11	MaxRel	0.62	
	F12	MaxNORel	0.643	
Concept groups	<i>MaxRelatednessCombined</i>		0.688	
			Strict	Full
	F13	AvgGroupSize	0.176	0.137
	F14	MaxGroupRel	0.655	0.481
	F15	MinGroupRel	0.002	0.001
	F16	AvgGroupRel	0.664	0.608
	F17	SDGroupRel	0.474	0.618
Overall	<i>GroupRelatednessCombined</i>		0.7	0.689
	F1-F17		0.808	0.799
			0.805	0.801

However, local centrality can still make a contribution. Imagine comparing three news stories, two of which discuss the cargo-ship Rena running aground off the coast of New Zealand, while the third places this in the broader context of other threats to local wildlife. All three documents are related, but for the third this is diluted by the

presence of other threads of discussion. This distinction is captured by local centrality. Consequently the *CentralityCombined* measure (with correlation of 0.774 and 0.759) performs better than relative centrality alone.

The “strongest connection” section of TABLE 3 shows that both these features strongly predict document similarity regardless of whether the binary or weighted representation is used. We do not consider the weakest concept connection—the minimum concept relatedness—because it barely correlates with human judgment (in fact, it is usually zero).

The distinction between the strict and full schemes—whether stray concepts that cannot be assigned to any groups are treated as singletons—affects all features in the “concept groups” section of TABLE 3, so their results are shown separately. All results were obtained using a relatedness threshold of 0.5 for creating concept cliques. The first feature—the averaged size of concept groups in each document (F13)—does not involve a concept’s number of occurrences in a document, so the binary and weighted schemes produce the same result. The minimum relatedness between concept groups (F15) contributes little, because even documents with similar topics usually mention some unrelated concepts, giving it a value close to zero. The average size of concept groups is not effective either, especially when compared with the other three features (F14–F17). As with the local centrality features, this is probably because it describes characteristics of the document itself, while the others target relations between documents.

All features except the first (F1, the bag-of-words representation) involve concepts and utilize the relatedness between them. If no concept is identified in a document, all their values are missing, and the model relies on F1 to make a prediction.

Removing Less-Informative Features

Five features stand out as significantly less informative than the others: the three local centrality features (F3, F4 and F6), the average concept group size (F13), and the minimum relatedness between concept groups (F15). Excluding these reduces the space from 17 features and 25 attributes to 12 features and 17 attributes. TABLE 4 compares the performance of the model trained before and after removing these features.

Discarding uninformative features is advantageous in most cases, although the differences are not statistically significant. TABLE 4 also shows that stray concepts are better ignored rather than treated as singleton clusters: the strict schemes outperform the full schemes and the improvements in both cases are statistically significant. Yet the difference between the two strict schemes—binary and weighted—is not significant.

TABLE 4 Performance of the reduced feature set on HE50.

Features (and their number of attributes)	Binary		Weighted	
	Strict	Full	Strict	Full
Full: F1–F17 (25)	0.808	0.799	0.805	0.801
Reduced: F1–F2, F5, F7–F12, F14, F16–F17 (17)	0.808	0.8	0.807	0.8

Evaluation in Document Classification and Clustering

In addition to the previous evaluation, we tested the learned measure in two applications: document classification and document clustering. Both benefit from an accurate measure of inter-document similarity.

In this evaluation, the full HE50 dataset is used to train the regression model, instead of using 10-fold cross-validation as before. This is safe because we are now testing the outcome on previously unseen data. The model is built with the *binary*

strict scheme and the reduced feature set—12 features and 17 attributes.

TABLE 5 Statistics of the four experimental datasets.

Dataset	Categories	Documents	Category Size
SmallReuters	30	1658	55.3
NewsSim3	3	2938	979.3
NewsDiff3	3	2780	926.7
Med100	23	2256	98.1

Test Data

We create four datasets from standard corpora whose thematic components are already labeled for evaluating classification and clustering performance.³ The first three, SmallReuters, NewsSim3 and NewsDiff3, contain short news articles and newsgroup posts covering diverse topics, while the last, Med100, contains medical papers from MEDLINE and is thus domain-specific. Each dataset has different properties, topic domains and difficulty levels. TABLE 5 shows summary statistics.⁴

Evaluation of Document Classification

Document classification is the task that automatically classifies a document into categories that are already known. There exist many classification methods, and we test the learned measure with instance-based classifiers (Aha, Kibler, & Albert, 1991), which predict the class of a test instance based on its closest (i.e. most similar) neighbor(s) in the training set, and thus require an accurate inter-document similarity measure. We use the standard k -nearest-neighbor classifier, denoted by k NN.

Classification performance is measured with the F_1 measure widely used in information retrieval. Let $\Omega = \{\omega_1, \dots, \omega_m\}$ denote the set of classes in the dataset. Given a class ω_i , $precision(\omega_i)$ and $recall(\omega_i)$ are defined as:

$$P(\omega_i) = \frac{\# \text{ documents in class } \omega_i \text{ that are classified as } \omega_i}{\# \text{ documents that are classified as } \omega_i},$$

$$R(\omega_i) = \frac{\# \text{ documents in class } \omega_i \text{ that are classified as } \omega_i}{\# \text{ documents in class } \omega_i}.$$

The F_1 measure is the harmonic mean of the two:

$$F_1 = \frac{2P(\omega_i)R(\omega_i)}{P(\omega_i)+R(\omega_i)}$$

The overall F_1 measure is the weighted sum of F_1 over all classes $\{L_1, \dots, L_m\}$ in the dataset:

$$F_1 = \sum_{\omega_i \in \Omega} \frac{|\omega_i|}{N} F_1(\omega_i),$$

where $|\omega_i|$ is the number of documents in class ω_i and N is the total number of documents in the dataset.

Overall Performance

We performed ten runs of 10-fold cross-validation with k NN on each dataset, and report the average classification performance. The best number of nearest neighbors in the range 1–10 was determined using leave-one-out cross-validation (Aha, et al., 1991).

TABLE 6 Performance of the learned measure in document classification.

	Word Cosine	Learned measure	
SmallReuters	0.881	0.924*	4.9%
NewsSim3	0.860	0.833**	-3.2%
NewsDiff3	0.971	0.976	0.5%
Med100	0.515	0.591**	14.8%

* statistically significant improvement/degradation

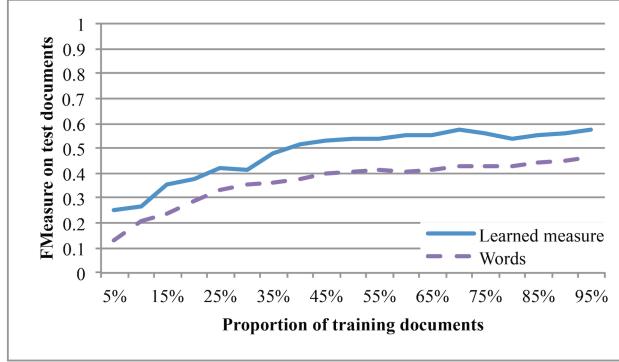

TABLE 6 compares the learned measure (using Wikipedia concepts) with the baseline method—the usual bag-of-words representation—and shows, using a paired t -test, whether or not the difference in performance is statistically significant. It achieves significant improvement on two datasets—SmallReuters and Med100. One possible reason why it fails to show improvement on the two newsgroup datasets is that NewsSim3 and NewsDiff3 contain only three classes and have many training examples—over 800 per class in each fold. This makes it more likely for a test instance to share considerable surface overlap with one of the training examples.

Varied Training Set

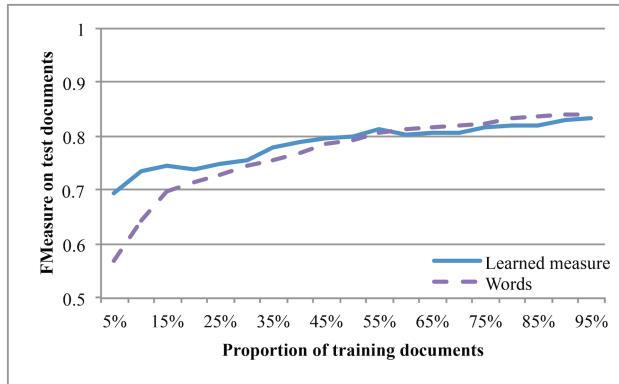

To investigate the impact of the likelihood that testing documents share surface overlap with training documents on classification performance, we varied the proportion of training examples from 5% to 95% in increments of 5%, and used the remaining examples for testing. Each of the 19 trials was run 10 times, with different training sets. The order of the training examples was randomized, and the best number of neighbors was sought as described above.

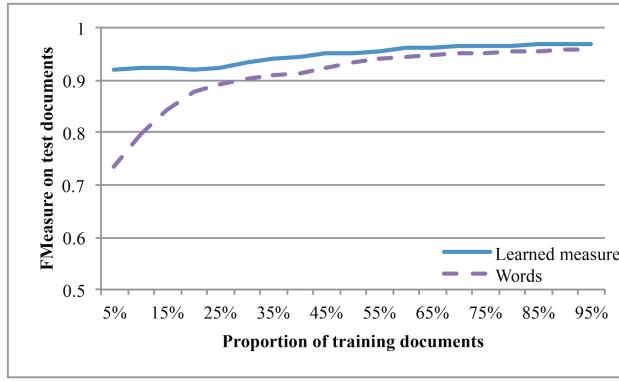

(a) SmallReuters

(b) Med100

(c) NewsSim3

(d) NewsDiff3

FIGURE 7 Learning curves for the four datasets.

FIGURE 7 shows the clear advantage of the learned measure for small training sets, particularly with NewSim3 (FIGURE 7c) and NewsDiff3 (FIGURE 7d). This suggests that it might be helpful when there is little overlap (of words or concepts) between the training and test examples, because the semantic connections between

concepts can effectively relate documents with similar topics but different surface forms.

Advantages of the learned measure are more consistent on the SmallReuters and the Med100 datasets. This is because the categories in the NewsSim3 and NewsDiff3 datasets are much larger: each category has about 900 documents on average. This means that taking 5% of the documents for training will result in about 45 training documents for each category, which is equivalent in size to taking 80% of the SmallReuters dataset and 45% of the Med100 dataset as training data. This indicates that the learned measure is particularly beneficial for problems with small training sets, which is important in practice because obtaining labelled training data is often expensive.

Evaluation of Document Clustering

Clustering is another important technique in practical data mining. Document clustering is the task that automatically analyzes the relations among documents and organizes them to form thematically coherent structures—clusters of documents that share similar topics. We tested two commonly used algorithms: hierarchical agglomerative clustering with group-average-link (Manning, et al., 2008) and k-means (Hartigan, 1975). Performance is measured in terms of goodness of fit with the existing categories in the dataset using the normalized mutual information (NMI) measure. For each dataset, the number of clusters being sought equals to the number of categories. Each cluster is labeled by the most frequent category in that cluster.

Let $\Phi = \{\rho_1, \dots, \rho_k\}$ and $\Omega = \{\omega_1, \dots, \omega_m\}$ denote the set of clusters and categories respectively. The NMI measure is defined as:

$$NMI(\Phi, \Omega) = \frac{I(\Phi; \Omega)}{[H(\Phi) + H(\Omega)]/2},$$

where I is the mutual information between the set of clusters and the set of categories, formally:

$$I(\Phi; \Omega) = \sum_{\rho_i} \sum_{\omega_j} \frac{|\rho_i \cap \omega_j|}{N} \log \frac{N |\rho_i \cap \omega_j|}{|\rho_i| |\omega_j|}.$$

Here, N is the total number of documents in the dataset, H is the entropy, and $H(\Phi)$ is defined as:

$$H(\Phi) = - \sum_{\rho_i} \frac{|\rho_i|}{N} \log \frac{|\rho_i|}{N},$$

and the same for $H(\Omega)$. Unlike other common measures for cluster quality, such as purity and inverse purity, NMI is independent of the number of clusters and can be used to measure the overall structural fitness of a clustering with respect to the categories (Manning, et al., 2008).

It is worth noting that the standard k-means algorithm represents a cluster by its centroid, and this representation differs from a normal document—for example, it has a non-zero value for every word or concept mentioned in any document in that cluster. Instead, we represented a cluster by its members, and measure its similarity to another document or group of documents by taking the average similarity with all member documents.

TABLE 7 shows the results. The learned similarity measure is very effective, and outperforms the baseline on every dataset. This is particularly remarkable in three respects. First, the training dataset is tiny—it only contains 50 documents—yet the learned measure can be effectively applied to larger corpora. Second, documents in the training dataset are significantly shorter than those in the experimental datasets—37 words compared to over 100 on average—yet the learned measure remains effective. Third, documents in the training dataset come from different sources and

cover different topics from those in the clustering dataset, which demonstrates that the learned measure is both generic and robust.

TABLE 7 Performance of the learned measure in document clustering.

	Hierarchical		<i>k</i> -means	
	Word Cosine	Learned measure	Word Cosine	Learned measure
SmallReuters	0.588	0.696*	0.687	0.792* :
Med100	0.276	0.365*	0.209	0.348*
NewsSim3	0.027	0.167*	0.008	0.298*
NewsDiff3	0.180	0.613* :	0.149	0.724*

* statistically significant improvement

The learned measure gains most on the NewsDiff3 dataset. This is because Wikipedia concepts are thematically dense descriptors—they provide topic-related information—while some words merely reflect lexical features and are common to documents with different topics. For example, adverbs and adjectives like *significantly* and *beautiful* rarely provide topic-related information. When the documents have very different topics, concepts can retain the main thematic features of a document and discard the unimportant lexical features, thus make the distinction even more prominent, which facilitates clustering.

Computational Complexity

Computational complexity mainly comes from two steps: the creation of document representations (i.e. bag of words and concepts) and application of the learned measure based on the representations. The first step is in general linear to the lengths of the two documents. Let w and c denote the average number of words and concepts found in a document. The overall complexity of the second step is quadratic

to the number of concepts and linear to the number of words. The Cosine similarity measure is linear: $O(w)$ and $O(c)$. Both the local and relative centrality measures are quadratic: $O(c^2)$. For the concept group features, we use the Bron-Kerbosch algorithm (Bron & Kerbosch, 1973) to find the maximal cliques, which has a $O(c)$ time complexity for sparse graphs. In practice, concept relatedness can be cached so as to speed up the computation of centrality measures. In practice, it usually takes a couple of seconds to predict for a pair from the experimental datasets.

Computational complexity of the training phase also contains two parts: the creation of document representations and training the regression model. The latter depends on the computational complexity of the regression method that is used, but is generally negligible with the amount of labeled training data that we deal with. As an indicative result, in our experiments training took less than one second with 17 attributes and 1225 training documents.

Conclusion

We have developed a novel method for learning an inter-document similarity measure from human judgment. It overcomes the redundancy, ambiguity and orthogonality problems that plague traditional methods of computing document similarity by using concepts instead of words as document descriptors and taking the semantic connections between concepts into account. The measure predicts similarity more consistently with average human raters than human raters do between themselves, and also outperforms the current state of the art on a standard dataset. Furthermore, both the features used for describing document similarity and the machine learning technique used to build the model are generic. The resulting measure applies to documents from different sources and topic domains, and

improves performance when classifying and clustering these documents: in the former case in particular when only a small amount of training data is present per class.

It is no surprise that concepts are better thematic descriptors of text than words. During the 1980s, researchers began to develop formal concept systems like WordNet to facilitate computer processing of natural language text, but success was limited and the bag-of-words model still prevails in practice. With the advent of Web 2.0 and the birth of collaboratively constructed, informal, yet comprehensive online encyclopedias such as Wikipedia, the use of concepts and their relations began to attract increasing attention as a replacement for words and other lexical features.

Our results provide strong support for why people should be encouraged to abandon the old models and methods. We have developed an alternative that is based on concepts, and have demonstrated that it is general and effective. The new method is not confined to the classification and clustering tasks tested here, but applies wherever text must be analyzed and organized according to its topics.

The results of this research are available in the form of an open source toolkit called Katoa (knowledge assisted text organization algorithms) that implements the concept-based document representations generator using WordNet and Wikipedia, and the similarity measure learned from human judgment.⁵
